Acknowledgments: Foremost, we would like to thank USAID for funding this research project through the 2019 DHS Fellows program implemented by ICF. We give thanks to our facilitators Dr. Shireen Assaf and Dr. Wenjuan Wang. Their scholarly guidance and encouragement was the source of energy for our research. We would like to express our special thanks to our co-facilitators, Mr. Gedefaw Abeje Fekade (Assistant Professor), and Dr. Kyaw Swa Mya for their invaluable assistance to improve our research during the training. We especially appreciate the support of Dr. Sorrel Namaste for her advice and sharing valuable materials at the inception that supports our inclusion criteria during sampling procedure. We also appreciate Rukundo Benedict and Yodit Bekele for their valuable comments and their time spent in sharing related materials to improve our work.

Editor: Bryant Robey

ABSTRACT

Background: The aim of this study was to examine the determinants of nutritional status among children under age 5 (0-59 months) in Ethiopia. Child malnutrition is an underlying cause of almost half (45%) of child deaths, particularly in low socioeconomic communities of developing countries. In Ethiopia, the prevalence of stunting decreased from 47% in 2005 to 39% in 2016, but the prevalence of wasting changed little over the same time period (from 11% to 10%). Despite improvements in reducing the prevalence of malnutrition, the current rate of progress is not fast enough to reach the World Health Organization global target for reducing malnutrition 40% by 2025.

Methods: This study used data from the 2016 Ethiopia Demographic and Health Survey (EDHS). The analysis used stunting and wasting as dependent variables, while the independent variables were characteristics of children, mothers, and households. Logistic regression was used to analyze the determinants of nutritional status among children. Bivariate analysis was also used to analyze the association between the dependent and independent variables.

Results: Study results show that child's age, sex, and perceived birth weight, mother's educational status, BMI, and maternal stature, and region, wealth quintile, type of toilet facility, and type of cooking fuel had significant associations with stunting. Child's age, sex, and perceived birth weight, mother's BMI, and residence and region showed significant associations with wasting.

Conclusions: The study found that child, maternal, and household characteristics were significantly associated with stunting and wasting among children under age 5. These findings imply that a multi-sectorial and multidimensional approach is important to address malnutrition in Ethiopia. The education sector should promote reduction of cultural and gender barriers that contribute to childhood malnutrition. The health sector should encourage positive behaviors toward childcare and infant feeding practices. More should be done to help households adopt improved types of toilet facilities and modern types of cooking fuels.

Key words: Stunting, wasting, children under age 5, Demographic and Health Survey, Ethiopia

1 INTRODUCTION

1.1 Background

Malnutrition during childhood is the outcome of insufficient food intake, diarrhea and other infections, lack of sanitation, and low parental education (Birara et al. 2014, Tibilla 2007). Poor diets and disease are due to food insecurity, inadequate maternal and child care, and poor health services and environment (UNAC 1997). These factors cause measurable adverse effects on body function and clinical outcome (WHO 2009). This problem leads to most of the anthropometric deficits found among under children under age 5 in the world's least developed countries (WHO 1995). Despite existing interventions to address child malnutrition, it is still a major global public health problem (Akombi et al. 2017). Child malnutrition is an underlying cause for almost half (45%) of child deaths, particularly in low socioeconomic communities of developing countries (Black et al. 2013). Globally in 2018, an estimated 149 million children under age 5 were stunted and 49 million children were wasted (UNICEF 2019).

In sub-Saharan Africa, the prevalence of stunting is declining but remains over 30% (UNICEF 2019). In order to address malnutrition, several African countries have updated their national nutrition policies, strategies, and action plans (African Union 2015). Among sub-Saharan countries, the prevalence of wasting in Ethiopia is 10%, and the prevalence of stunting is 38% (CSA 2016). Within Ethiopia, there is a regional variation in stunting and wasting. Amhara, Benishangul-Gumuz, Afar, and Dire Dawa are the most affected by child stunting (41-46%), whereas wasting is highest in Somali (23%), Afar (18%), and Gambella (14%) (CSA 2016). The reason may be hard-to-reach areas of Afar, Somali, Benishangul-Gumuz, and Gambella were characterized by drought-related public health and nutrition problems (UNICEF 2017). The current rate of progress is not fast enough to reach the World Health Organization (WHO) global target of a 40% reduction in the number of stunted children by 2025 (WHO 2014).

Thus to achieve this global target for 2025 in Ethiopia, a situational analysis is required to determine how many children under age 5 are stunted and wasted and to assess key determinants of malnutrition in specific social and geographical locations (WHO 2014). This type of analysis will provide evidence for program intervention so that programmatic actions can be tailored to address the contextual needs in Ethiopia.

1.2 Literature Review

Among the factors that cause child malnutrition in Ethiopia are insufficient availability of food, inadequate provision of a healthy environment, such as sanitation and hygiene, women's status concerning decision-making power, and factors related to political economy (Hutton and Chase 2016, Shroff et al. 2009). Some studies have linked low birth weight, maternal short stature, household wealth quintile, place of residence, region, mother's education, child's age and sex, and perceived birth size to children's nutritional status (Mamabolo et al. 2005, Novignon et al. 2015). However, other studies (Gayle et al. 1987, Uthman 2009, Wamani et al. 2007) have found consistent disparities in the prevalence of child malnutrition in terms of children's age, sex, and birth size.

At the policy and program level, Ethiopia has many strategies and programs to reduce levels of malnutrition as part of its national development agenda. Some of the major strategies and programs include: the growth and transformation plan (GTP), National Nutrition Plan (NNP), the Seqota Declaration (SD), National Food Security Strategy, Nutrition Sensitive agriculture (NSa) strategy, school health and Nutrition Strategy (ShNS), the Productive Safety Net Program (PSNP), and Food Safety and Quality related regulatory activities (FDRE Food and Nutrition Policy 2018). The Seqota Declaration adopted Sustainable Development Goal 2 (SDG2), with the aim to end hunger, achieve food security, and improve nutrition, and promote sustainable agriculture by 2030 (Seqota Declaration 2016).

The Government of Ethiopia through the Ministry of Health also launched the health extension program in 2003 to achieve the country's progress in meeting the Millennium Development Goals (MDGs). The health extension workers are mainly to improve access to care in rural communities. They spend 15% of their time with infants and children under age 5 (Mangham-Jefferies et al. 2014). All of these listed efforts have brought positive impact in improving food and nutrition security (FDRE Food and Nutrition Policy 2018). However, there was a fragmented approach leading to inadequate multi-sectorial coordination in responding to food and nutrition demand. As a result, severe malnutrition has remained a serious challenge (FDRE Food and Nutrition Policy 2018). Therefore, the rationale of the food and nutrition policy is to use efforts and resources in integrated and clear directions and strategies, so as to bring better results. Thus, this finding will be used as a source of information to implement the newly introduced national food and nutrition policy.

1.3 Rationale of the Study

Despite efforts made by the Ethiopian government and improvements in reducing malnutrition, at the current rate of progress it will be difficult to reach the global target for reducing malnutrition by 2025. There are few comprehensive studies in Ethiopia based on nationally representative data to identify determinants of malnutrition among children under age 5. This study is designed to address the gaps in previous studies that used only some determinant variables at a time, whereas the current study uses many determinant variables at the same time, which will help to generalize the study findings at the national level. This study will help health practitioners and other policymakers to enable a multi-sectoral response to malnutrition by identifying its determinants among children under age 5. This is important to achieving the Sustainable Development Goals and to meeting the global target by 2025. Understanding the extent and the causes of the problem will allow for appropriate planning and interventions.

1.4 Research Question

This study was designed to answer the following specific research question;

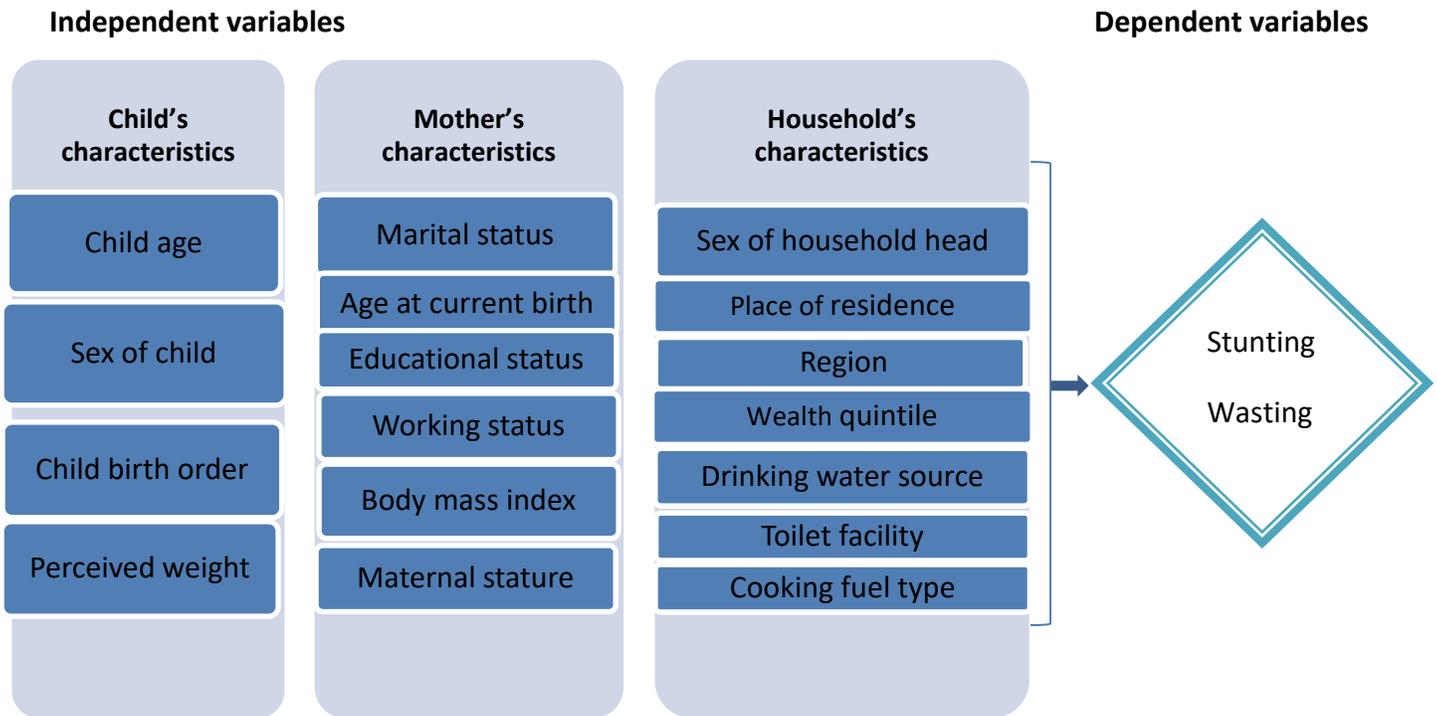

- What are the determinant factors of malnutrition in children under age 5 in 2016 in Ethiopia?

1.5 Conceptual Framework

The conceptual framework of this study (Figure 1) was developed from the related literature, including a report on the causes and consequences of stunted growth published by WHO (WHO 2017). Our study used children's characteristics (age, sex, birth order, and perceived birth weight), maternal characteristics (sex of the household head, marital status, age at current birth, educational status, working status, body mass

index, and maternal stature), and household characteristics (place of residence, region, wealth quintile, water sources, toilet facilities, and cooking fuel types) as determinant factors. The dependent variables in this study were stunting and wasting among children under age 5 in Ethiopia.

Figure 1 Conceptual framework to study determinants of nutritional status among children under 5 in Ethiopia

2 DATA AND METHODS

2.1 Data

This study used data from the 2016 Ethiopia Demographic and Health Survey (EDHS), which was conducted by the Central Statistical Agency (CSA) of Ethiopia, with technical support from ICF. The EDHS is a population-based household survey designed to provide representative data for the country as a whole and for nine regional states and two city administrations of Ethiopia. This study considered live children age 0-59 months with anthropometry data in the analysis of determinants of nutritional status among children under age 5 in Ethiopia. Missing values in the 2016 EDHS dataset were not included in the analyses. Not-alive children (635) and children with no anthropometry data from stunting condition (1000) or wasting condition (927) were also omitted from the analysis.

2.2 Variables

2.2.1 Dependent variables

The three anthropometric indicators mostly used for monitoring malnutrition in children are: stunting (low height-for-age); underweight (low weight-for-age); and wasting (low weight-for height). However, underweight is the composite of stunting and wasting, so this study used stunting and wasting for the analysis. They were defined using the WHO (2006) child growth standards. Stunting and wasting were coded as binary variables based on the standard definitions.

2.2.2 Independent variables

As illustrated in the conceptual framework (Figure 1), to analyze the determinants of nutritional status among children under age 5, the study considered the following characteristics as independent variables: 1) child characteristics, including age (less than 6 months, 6-11 months, 12-17 months, 18-23 months, and 24-59 months), sex (male, female), birth order (first, 2-4, 5 or higher), and perceived birth weight (very small, smaller than average, average, and very large or larger than average); 2) maternal characteristics, including marital status (never married, married, widowed/divorced/separated), age at child's birth (12-19, 20-49), educational status (no education, primary, secondary and above), working status (yes, no), body mass index (underweight, normal, overweight), and maternal stature (normal stature, short stature); 3) household characteristics, including place of residence (urban, rural), region (nine regions and two city administrations), wealth quintile (poorest, poorer, middle, rich, and richest), drinking water source (improved, non-improved), toilet type (improved, non-improved), and cooking fuel type (modern, traditional).

In the DHS, wealth quintile is calculated as an index based on consumer goods such as television, bicycle, or car. Household characteristics such as toilet facility, source of drinking water, and flooring materials are also considered in calculating the wealth index. These scores were derived using principal component analysis. Based on the 2016 EDHS, the water sources and toilet facilities were recoded as either improved or non-improved. Piped water, public taps, standpipes, tube wells, boreholes, protected dug wells and springs, and rainwater were considered as improved water sources. Non-shared toilet of the following types: flush/pour flush toilets to piped sewer systems, septic tanks, and pit latrines; ventilated improved pit (VIP)

latrines; pit latrines with slabs. Composting toilets were considered as improved toilet facilities for this analysis. For household fuel type, electricity, natural gas, biogas, and kerosene were categorized as modern fuel. Charcoal, wood, animal dung, and other agricultural crops and straw were considered as traditional fuel.

2.3 Statistical Analysis

Descriptive statistics were used to describe and illustrate the background characteristics of children age 0-59 months. Stata 15.1 version was used to analyze the data. Sample weights were applied in all analysis due to the two-stage cluster sampling design in the EDHS dataset. Multicollinearity among independent variables was checked using variance inflation factors (VIF). Due to multicollinearity, preceding birth interval was removed from the analysis. Multiple logistic regression was used to determine the associations between predictors and nutritional outcomes after adjusting for other covariates. The study also used Pearson chi-square test for bivariate analysis.

3 RESULTS

3.1 Sample Characteristics

As Table 1 shows, the majority of children (61%) were age 24-59 months, more than half (51%) were male, and 18% were first-order births. The great majority of mothers were married (95%), age 20-49 (90%), and not working (72%). About three-fourths of mothers (74%) had normal body mass index (BMI). The large majority of households (86%) were male-headed, and 89% were in the rural areas of Ethiopia. By region, over three-quarters of children were located in just three regions: 19% in Amhara; 44% in Oromia; and 21% in SNNP. Nearly half of households (46%) were in the poorest or poorer wealth quintiles, versus a third (33%) in the richer or richest quintiles.

3.2 Bivariate Associations of Stunting and Wasting by Background Characteristics

Table 2 indicates results from the bivariate analyses. Characteristics significantly associated with stunting included child’s age, sex, birth order, perceived weight, maternal education, mother’s BMI, place of residence, region, wealth quintile, toilet type, and fuel type. Variables associated with wasting included child’s age, perceived weight, mother’s BMI, region, wealth quintile, and fuel type.

Traditional fuel	39.1	[37.2,41.1]		10.1	[9.1,11.3]	

3.3 Factors Associated with Stunting

Table 3 shows the results of the adjusted multiple logistic regressions for stunting and wasting. Child's age had a significant association with stunting. Children in the three age groups between 12-59 months were significantly more likely to be stunted compared with children age 0-6 months, with the highest odds found among children age 18-23 months. Female children were less likely to be stunted than male children. Children perceived as very large or larger than average in weight at birth were less likely to be stunted compared with children perceived as very small. Children of mothers with secondary and above educational attainment were less likely to be stunted compared with children of mothers with no education.

Children born of overweight and normal-BMI mothers were significantly less likely to be stunted compared with children of underweight mothers. Children of short-stature mothers were more likely to be stunted compared with children of not-short-stature mothers. There was significant regional variation in stunting among children under age 5. Children from Amhara region were more likely to be stunted compared with Tigray region. In contrast, children from Addis Ababa, Gambella, and Somali regions were less likely to be stunted. Children from the richest, richer, and middle household wealth quintiles were less likely to be stunted compared with children from the poorer and poorest quintiles. Children in households with non-improved toilet facilities were more likely to be stunted compared with those with improved toilet facilities. Children in households with traditional cooking fuel type were more likely to be stunted compared with those with modern fuel type.

3.4 Factors Associated with Wasting

Table 3 also presents results of the adjusted multiple logistic regression for wasting. Children age 24-59 months were significantly less likely to be wasted compared with children age 0-6 months. Children with larger than average weight at birth and children with average perceived weight at birth were less likely to be wasted compared with children with perceived as very small at birth. Female children were less likely to be wasted than male children. Children whose mothers were overweight or of normal BMI had lower odds of being wasted compared with children of underweight mothers. Rural children were less likely to be wasted compared with urban children. Children in households in Addis Ababa and SNNP had lower odds

of being wasted compared with children in Tigray region, while children in households in Somali region had higher odds of being wasted.

4 DISCUSSION

This study assessed the determinants of nutritional status among children under age 5 in Ethiopia. Study results show that child's age, sex, and perceived birth weight, mother's educational status, BMI, and maternal stature, and region, wealth quintile, type of toilet facility, and type of cooking fuel had significant associations with stunting. Child's age, sex, and perceived birth weight, mother's BMI, and residence and region showed significant associations with wasting.

This study shows that the risk of stunting increased with age of child. Previous studies in Ethiopia have shown similar results (Asfaw and Giotom 2000; Genebo et al. 1998; Yimer 2000). The reason might be that as children grow older they have greater energy needs. Besides, stunting reflects chronic malnutrition that can be manifested after long-term nutritional deficiency, while wasting reflects acute undernutrition. As child's age increases, there is the probability that the child will receive childhood vaccinations, which reduce exposure to disease. For example, Mekonnen et al. (2005) found that children vaccinated against measles are less likely to be wasted.

In Ethiopia as in many developing countries, complementary feeding is a challenge for children age 6-23 months (Abeshu et al. 2016). Studies in other developing countries by Caulfield et al. (1999), Mora and Nestel (2000), and Abeshu et al. (2016) found that complementary foods given to infants in the second six months of age and beyond are often inadequate in energy density.

In our study, female children were less likely to be stunted and wasted than boys. This finding is consistent with a meta-analysis in sub-Saharan Africa (Wamani et al. 2007), a study in the Northern Ethiopia (Alemayehu et al. 2015), and research in Myanmar (Mya et al. 2019). However, it is contrary to findings of studies in Tanzania (Mbago and Namfua 1992), Pakistan (Baig-Ansari et al. 2006), India (Mittal et al. 2007), and Kenya (Gewa and Yandell 2012) that girls had a higher prevalence of stunting than boys. Garenne (2003), Bork and Diallo (2017), and Wamani et al. (2007) found that sex differences in nutritional status might be due to biological differences in morbidity between boys and girls in their early life. This may also apply to our findings on wasting. A review of complementary feeding reported that boys have higher birth weights than girls and grow faster during infancy, resulting in greater energy needs (Bork and Diallo 2017). Furthermore, another study on Guatemalan infants reported that women perceived male children to be hungrier and less likely to be satisfied by breastfeeding alone (Tumilowicz et al. 2015), placing them at increased risk of infections.

Regarding our findings on perceived weight of child at birth, the risks of stunting and wasting were higher among children perceived to have low birth weight. These findings are consistent with previous studies in Zambia (Masiye et al. 2010), Bangladesh (Dhar et al. 2002; Islam et al. 2013; Jesmin et al. 2011), India (Mishra et al. 2014), Malaysia (Wong et al. 2014), and Indonesia (Rahman et al. 2016), and may be due to the poor nutrition of mothers during pregnancy. This finding is supported by our results of the association between mother's BMI and stunting and wasting in children. Ramakrishnan (2004) reported that children born of overweight mothers are less likely to be stunted and wasted due to adequacy of protein and energy intakes of mothers during pregnancy (Ramakrishnan 2004). A similar study in Nepal (Prasad Singh et al. 2009) also showed that as maternal BMI increased there was a reduction in children's stunting, and wasting.

Our study found that children born to mothers with short stature were more likely to be stunted. This result is in line with previous studies in South Africa (Mamabolo et al. 2005; and Ghana Novignon et al. 2015). This association reflects the fact that women who were stunted during their own childhood are more likely to give birth to stunted children (Reynaldo Martorell and Zongrone 2012).

Higher level of mothers' educational attainment was positively associated with stunting in children. This is in line with previous related studies in the Philippines (Aguillon et al. 1982), Libya (Popkin and Bisgrove 1988), Ethiopia (Yimer 2000), Uganda (Wamani et al. 2004), Mozambique (Burchi 2010), and Ghana (Novignon et al. 2015). As stated in different studies, the reasons include that educated women are better informed about optimal child care practices (Oyekale 2012), have better hygiene practices (Keats 2018, Smith and Haddad 2000), feeding (Mukabuteru et al. 2016), and childcare during illness (Bhutta et al. 2008; Iannotti et al. 2013; Mukabuteru et al. 2016), have a greater ability to use the health system (Sunguya et al. 2014), and are more empowered to make decisions (Keats 2018). In our study, however, in about two-thirds of cases (65%), the mothers had not attended formal education, and as a result their knowledge on childcare may not have been enough.

Our study found regional variation in stunting and wasting in Ethiopia. Compared with Tigray, the reference region, children from Addis Ababa were less likely to be either stunted or wasted, while children in Gambella were less likely to be stunted, and children in SNNP were less likely to be wasted. Interestingly, children in the Somali region were less likely to be stunted but more likely to be wasted compared with Tigray. This could be because wasting is characterized by acute malnutrition that can be caused by temporary increased food insecurity from extreme weather events, drought, and shifts in agricultural practices (McCarthy et al. 2001, Swinburn 2019). Previous research in Ethiopia (Pelletier et al. 1995) showed the association between malnutrition varied across regions due to variation in cultivated area.

We found that children from the richest, richer, and middle household wealth quintiles were less likely to be stunted compared with children from the poorer and poorest quintiles. As mentioned, in the DHS surveys household wealth is measured as an index reflecting household material living standards, which include the types of water sources and sanitation facilities used by the household. Our study found that children in households with non-improved toilet facilities and traditional fuel types were more likely to be stunted. Previous studies in Nepal (Headey and Hoddinott 2015) and other Asian countries (Headey et al. 2016) have found that household asset accumulation is an important predictor of nutritional improvement.

Environmental factors such as unimproved water, unimproved sanitation, and biomass fuel are the second largest global attributable burden as cause of child stunting (Danaei et al. 2016). A study of 137 developing countries reported that an estimated 7.2 million cases of stunting were attributable to unimproved sanitation (Danaei et al. 2016). In Ethiopia, more than half of rural households (56%) use unimproved toilet facilities (CSA 2016). In rural areas of Ethiopia, more than one in three households (39%) have no toilet facility, versus 7% in urban areas (CSA 2016). Related studies in Sri Lanka (De Silva et al. 1994; Gunawardena et al. 2004; Gunawardena et al. 2011; Sorensen et al. 1996) revealed that malnutrition among children is still a major health problem associated with poor sanitation and personal hygiene. However, a study conducted in rural Zimbabwe (Humphrey et al. 2018) found improved water, sanitation, and hygiene interventions in rural areas in low-income countries were unlikely to reduce stunting more than the effect of improved infant and child feeding alone. This implies integration of improved infant diets with improved water, sanitation, and hygiene is a logical approach to improve nutritional status of under-five children.

The great majority of Ethiopian households (93%) use traditional fuels such as wood, charcoal, and dung cake to meet their daily needs, and most households (59%) cook food outside (CSA 2016). Ramakrishnan (2004) found that indoor air pollution and smoking are causes of low birth weight and could possibly impact stunting. Another study in India reported associations between air pollution and stunting (Mishra and Retherford 2007); children living in households using biofuel were more likely to be stunted compared with children living in households using cleaner fuels.

5 STRENGTHS AND LIMITATIONS

The strength of this study was that it used nationally representative data, which allow generalization of the results; it also applied all of the DHS data principles, like weighting. Regarding limitations, the cross-sectional data cannot examine causation or seasonal variation of nutritional outcomes. The other limitation is that during DHS data collection measurements of children's height obtained by laying down children under age 2 may be considered as a source of human error.

6 CONCLUSION AND POLICY LIMITATIONS

Our study found that child, maternal, and household characteristics were significantly associated with stunting and wasting among children under age 5. Despite efforts made by the Ethiopian government and improvements in reducing malnutrition, rates of stunting and wasting remain high. The consequences of child malnutrition are grave and include poor performance in school and low adult economic productivity. The findings imply that a multi-sectorial and multidimensional approach is important to address malnutrition in Ethiopia. The education sector should promote maternal education and policies to reduce cultural and gender barriers. The health sector should provide health education to families to encourage positive behaviors toward childcare and infant feeding practices. In addition, the health and human services sectors can promote use of improved toilets. To reduce stunting due to traditional fuel usage in households, the energy sector should help households to access clean energy. Further research is suggested to explore the impact of seasonal food insecurity and climatic events on stunting and wasting and to examine the associated factors affecting nutritional status among children over time, using decomposition analysis.
